## Lab Experiment 4 — A\* (A-Star) Algorithm

6th Semester · B.Tech Computer Science & Engineering · NIT Srinagar

|              |  |                |  |
|--------------|--|----------------|--|
| Student Name |  | Enrollment No. |  |
| Batch        |  | Date           |  |

**Instructions:** Answer all 4 scenario-based problems. For each problem: (a) build the graph/state representation, (b) fill the A\* open-list trace table, (c) write Python code using `heapq`, and (d) answer the analysis questions. A\* uses  $f(n) = g(n) + h(n)$ . Always pop the node with **lowest**  $f(n)$ .

## Quick Reference — A\* Algorithm

| Property             | Value                                                      | Reason                              |
|----------------------|------------------------------------------------------------|-------------------------------------|
| Evaluation function  | $f(n) = g(n) + h(n)$                                       | Actual cost + heuristic estimate    |
| $g(n)$               | Actual cost: start $\rightarrow n$                         | Tracked as we expand nodes          |
| $h(n)$               | Heuristic: $n \rightarrow$ goal                            | Must be admissible for optimality   |
| Data structure       | Min-Heap on $f(n)$                                         | <code>heapq</code> in Python        |
| Admissible heuristic | $h(n) \leq h^*(n)$                                         | Never overestimates true cost       |
| Complete?            | Yes                                                        | Finds solution if one exists        |
| Optimal?             | Yes (admissible $h$ )                                      | Guaranteed shortest/cheapest path   |
| Time complexity      | $O(b^d)$                                                   | $b$ = branching factor, $d$ = depth |
| Space complexity     | $O(b^d)$                                                   | Stores all generated nodes          |
| vs Best-First        | BFS* uses only $h(n)$                                      | A* adds $g(n)$ , so it is optimal   |
| Python: push         | <code>heapq.heappush(open_list, (f, g, node, path))</code> |                                     |
| Python: pop          | <code>heapq.heappop(open_list)</code><br>gives lowest $f$  |                                     |

### Scenario: Optimal Route Between Cities

A smart navigation app has a road network of **8 cities** (A–H). A driver must travel from city **A** to city **H**. Unlike Best First Search, the app uses **A\*** to guarantee the **cheapest** total route, not just the one that looks closest.

**Road network (city – city : road distance km):**

A–B(4), A–C(3), B–D(5), B–E(2), C–E(6), C–F(4), D–H(8), E–H(5), F–G(3), G–H(2)

**Heuristic**  $h(n)$  = straight-line distance to H:

| City        | A  | B | C | D | E | F | G | H |
|-------------|----|---|---|---|---|---|---|---|
| $h(n)$ (km) | 10 | 8 | 7 | 5 | 4 | 6 | 2 | 0 |

**Tricky part:** Best First Search (Lab 3) found path  $A \rightarrow C \rightarrow E \rightarrow H = 14$  km. A\* should find the true cheapest path by tracking  $g(n)$  as well. Which path does A\* find? Is it different from Best First Search?

### Tasks:

- For each node below, write  $g(n)$ ,  $h(n)$ , and  $f(n)$  when A\* first reaches it from A. [4 Marks]
- Fill the A\* open-list trace table (expand until H is popped). [6 Marks]
- Write Python A\* code using `heapq`. Push (f, g, node, path). [8 Marks]
- Compare:** What path did Best First Search find (Lab 3)? What does A\*

find? Why are they different?

[2 Marks]

(a)  $g$ ,  $h$ ,  $f$  values when first reached:

| Node | $g(n)$ (actual cost from A) | $h(n)$ (given) | $f(n) = g + h$ | Reached via |
|------|-----------------------------|----------------|----------------|-------------|
| B    |                             | 8              |                |             |
| C    |                             | 7              |                |             |
| D    |                             | 5              |                |             |
| E    |                             | 4              |                |             |
| F    |                             | 6              |                |             |
| G    |                             | 2              |                |             |
| H    |                             | 0              |                |             |

(b) A\* Open-List Trace (pop lowest  $f$  each step):

| Step | Pop node | $g$ | $f = g + h$ | Open list (node:f) after pop |
|------|----------|-----|-------------|------------------------------|
| 0    | —        | —   | —           | A:10                         |
| 1    |          |     |             |                              |
| 2    |          |     |             |                              |
| 3    |          |     |             |                              |
| 4    |          |     |             |                              |
| 5    |          |     |             |                              |
| 6    |          |     |             |                              |

Optimal path: \_\_\_\_\_ Total cost: \_\_\_\_\_ km

(c) Python Code:

(d) Comparison with Best First Search:

**Scenario: Warehouse Robot Shortest Route**

A warehouse robot must navigate a **5×5 grid** from the top-left corner **(0,0)** to the bottom-right corner **(4,4)**. Cells marked **1** are blocked shelving units. The robot moves Up, Down, Left, Right. Each move costs **1 unit**.

**Grid** (0 = passable, 1 = blocked):

|   |   |   |   |   |
|---|---|---|---|---|
| 0 | 0 | 1 | 0 | 0 |
| 0 | 1 | 0 | 0 | 0 |
| 0 | 0 | 0 | 1 | 0 |
| 0 | 1 | 0 | 0 | 0 |
| 0 | 0 | 0 | 1 | 0 |

**Heuristic:** Manhattan distance to (4,4):  $h(r,c) = |4-r| + |4-c|$

**Tricky part:** Two blocked clusters create detours. A\* tracks  $g(n)$  = actual steps taken so far +  $h(n)$  = Manhattan distance remaining. It will always find the minimum-step path, unlike Best First Search.

**Key difference from BFS\* (Lab 3):** In Lab 3, the grid robot used Best First Search and was *not* guaranteed to find minimum steps. A\* adds  $g(n)$  = steps taken so far.  $f(n) = g(n) + h(n)$  ensures the minimum-cost (fewest steps) path is found.

**Tasks:**

1. Calculate  $h(r,c)$  for: (0,0), (2,2), (4,3). **[3 Marks]**
2. Trace A\* for the first **5 expansion steps** from (0,0). Show  $g$ ,  $h$ ,  $f$  for each cell when pushed to open list. **[6 Marks]**
3. Write complete Python A\* code for the grid. Requirements: **[9 Marks]**
  - State = tuple (row, col)
  - Open list entry = (f, g, (row,col), path)
  - Skip blocked cells & out-of-bound positions
  - Print the path and total steps
4. **Analysis:** If all cells were unblocked, what would the minimum steps be from

$(0,0)$  to  $(4,4)$ ? Does  $A^*$  find it? Explain.

**[2 Marks]**

(a) Heuristic values:

$$h(0,0) = \underline{\hspace{2cm}} \qquad h(2,2) = \underline{\hspace{2cm}} \qquad h(4,3) = \underline{\hspace{2cm}}$$

(b) First 5 A\* expansion steps:

| Step | Pop cell | $g$ | $h$ | $f = g + h$ | Neighbours pushed |
|------|----------|-----|-----|-------------|-------------------|
| 0    | (0,0)    | 0   | 8   | 8           | (0,1) and (1,0)   |
| 1    |          |     |     |             |                   |
| 2    |          |     |     |             |                   |
| 3    |          |     |     |             |                   |
| 4    |          |     |     |             |                   |

(c) Python Code:

(d) Minimum steps analysis (unblocked grid):

Minimum steps (unblocked) = \_\_\_\_\_ Does A\* find it? \_\_\_\_\_ Why? \_\_\_\_\_

**Scenario: Sliding Tile Puzzle**

The **8-puzzle** is a  $3 \times 3$  grid with tiles numbered 1–8 and one blank space (0). Tiles slide into the blank. Find the **minimum number of moves** to reach the goal configuration from the given start.

**Start State**

|   |   |   |
|---|---|---|
| 1 | 2 | 5 |
| 3 | 4 | 0 |
| 6 | 7 | 8 |

**Goal State**

|   |   |   |
|---|---|---|
| 1 | 2 | 3 |
| 4 | 5 | 6 |
| 7 | 8 | 0 |

**Heuristic 1 (Misplaced Tiles):**  $h_1(s)$  = number of tiles not in their goal position (excluding blank).

**Heuristic 2 (Manhattan Distance):**  $h_2(s) = \sum_{\text{tile } t} |r_t - r_t^*| + |c_t - c_t^*|$  where  $(r_t, c_t)$  is current position and  $(r_t^*, c_t^*)$  is goal position.

**Tricky part:** Both heuristics are admissible, but  $h_2 \geq h_1$  always (Manhattan is more informed). A\* with  $h_2$  expands *fewer* nodes than A\* with  $h_1$ . You must implement **both** and compare.

State representation: flat tuple (1,2,5,3,4,0,6,7,8), blank = index of 0.

**Tasks:**

1. Calculate  $h_1$  and  $h_2$  for the given start state. Show tile-by-tile working for  $h_2$ .

**[5 Marks]**

2. Write the A\* algorithm pseudocode for the 8-puzzle (state-space search).

**[4 Marks]**

3. Write Python A\* code that:

**[9 Marks]**

- Represents state as a tuple of 9 integers
- Generates all valid moves (slide blank Up/Down/Left/Right)
- Uses **Manhattan Distance** as heuristic
- Prints move sequence and total moves

4. **Tricky:** Why is Manhattan distance **admissible**? Can  $h(n) > h^*(n)$ ? What happens to A\* if the heuristic is not admissible? [2 Marks]

(a) **Heuristic calculations for start state (1,2,5,3,4,0,6,7,8):**

$h_1$  (misplaced tiles): Tiles out of place = \_\_\_\_\_  $h_1$  = \_\_\_\_\_

$h_2$  (Manhattan distance) tile-by-tile:

| Tile        | Current pos | Goal pos | $ \Delta r $ | $ \Delta c $ | Distance |
|-------------|-------------|----------|--------------|--------------|----------|
| 1           | (0,0)       | (0,0)    | 0            | 0            | 0        |
| 2           | (0,1)       | (0,1)    | 0            | 0            | 0        |
| 5           |             | (1,1)    |              |              |          |
| 3           |             | (0,2)    |              |              |          |
| 4           |             | (1,0)    |              |              |          |
| 6           |             | (1,2)    |              |              |          |
| 7           |             | (2,0)    |              |              |          |
| 8           |             | (2,1)    |              |              |          |
| Total $h_2$ |             |          |              |              |          |

(b) **Pseudocode:**

(c) **Python Code:**

(d) Admissibility analysis:

### Scenario: Internet Packet Routing

A network has **10 routers** (R0–R9). A data packet must travel from **router R0** to **router R9** with the **minimum total latency** (ms). Each link has a latency cost. The network engineer uses A\* with  $h(n)$  = estimated remaining latency to R9 (from network topology knowledge).

**Network links (router – router : latency ms):**

R0–R1(4), R0–R2(7), R1–R3(3), R1–R4(6), R2–R4(2), R2–R5(5),  
R3–R6(5), R4–R6(3), R4–R7(4), R5–R7(6), R6–R9(8),  
R7–R8(2), R8–R9(3)

**Heuristic**  $h(n)$  = estimated latency to R9:

| Router      | R0 | R1 | R2 | R3 | R4 | R5 | R6 | R7 | R8 | R9 |
|-------------|----|----|----|----|----|----|----|----|----|----|
| $h(n)$ (ms) | 18 | 14 | 12 | 10 | 8  | 10 | 7  | 5  | 3  | 0  |

**Tricky part:** There are multiple plausible paths (via R6 or via R8), and the heuristic for R2 is 12 but R2 leads quickly to R4 which reaches R8 — a short, cheap final hop. A\* must correctly balance  $g(n)$  and  $h(n)$  to find the global optimum, not just follow low- $h$  nodes greedily.

### Tasks:

1. **Identify two possible paths** from R0 to R9 (without running the algorithm) and compute their actual costs manually. [4 Marks]
2. Fill the A\* open-list trace. Pop until R9 is expanded. [7 Marks]

3. Write Python A\* code. Output must include:

[9 Marks]

- Each node expanded with its  $g$ ,  $h$ ,  $f$  values
- The optimal path
- Total latency in ms

4. **Tricky:** Is the given  $h(n)$  admissible? Verify for R2: actual shortest cost R2→R9 vs  $h(R2) = 12$ .

[ Marks]

(a) Two candidate paths and their costs:

Path 1: \_\_\_\_\_ Cost = \_\_\_\_\_ ms

Path 2: \_\_\_\_\_ Cost = \_\_\_\_\_ ms

(b) A\* Open-List Trace:

| Step | Pop | $g$ | $h$ | $f$ | Open list (router:f) after |
|------|-----|-----|-----|-----|----------------------------|
| 0    | —   | —   | —   | —   | R0:18                      |
| 1    |     |     |     |     |                            |
| 2    |     |     |     |     |                            |
| 3    |     |     |     |     |                            |
| 4    |     |     |     |     |                            |
| 5    |     |     |     |     |                            |
| 6    |     |     |     |     |                            |
| 7    |     |     |     |     |                            |

Optimal path: \_\_\_\_\_ Total latency: \_\_\_\_\_ ms

(c) Python Code:

(d) Admissibility check for R2:

Actual shortest cost R2→R9 = \_\_\_\_\_ ms

$h(R2) = 12$  ms

Is  $h(R2) \leq$  actual cost? \_\_\_\_\_ Is heuristic admissible? \_\_\_\_\_

---
